Abstract

The rapid proliferation of Internet of Things (IoT) devices has created unprecedented volumes of network traffic that organizations must migrate and manage using cloud infrastructure. Accurate prediction of migration costs remains a critical challenge due to the dynamic, heterogeneous nature of IoT traffic and the complexity of multi-provider cloud pricing. This paper presents an Adaptive Machine Learning Framework for IoT Migration Cost Prediction that addresses these challenges using the RT-IoT2022 dataset comprising 123,117 real IoT network flows and 85 features. We train and compare four machine learning models — Linear Regression, Decision Tree, Random Forest, and XGBoost — achieving R^2= 0.9996 and MAPE= 3.45% with Random Forest as the best model. Statistical significance testing confirms Random Forest significantly outperforms both Linear Regression ($p \approx 0$) and XGBoost ($p = 0.001$). An adaptive sliding window retraining framework continuously updates predictions as IoT traffic evolves, achieving 88.4% MAE improvement over 10 retraining windows. SHAP analysis provides per-flow prediction explanations, identifying flow duration as the dominant cost predictor. A novel multi-cloud cost optimizer evaluates 4,432,212 combinations across AWS, Azure, and GCP — balancing 70% financial cost and 30% carbon footprint — achieving 42.9% average savings per IoT flow. The entire framework is automated via a single pipeline command, making it production-ready for enterprise IoT deployments.

Keywords: IoT migration, cloud cost prediction, machine learning, adaptive retraining, multi-cloud optimization, carbon footprint, XGBoost, Random Forest, SHAP explainability.

1. Introduction

The Internet of Things (IoT) represents one of the most transformative technological shifts of the 21st century. By 2025, over 75 billion IoT devices are expected to be operational globally, generating data volumes that exceed the capacity of local infrastructure to process and store [10]. Organizations across manufacturing, healthcare, smart cities, and industrial automation are increasingly migrating IoT workloads to cloud platforms such as Amazon Web Services (AWS), Microsoft Azure, and Google Cloud Platform (GCP). The global cloud market, valued at over $500 billion in 2023, continues to grow as this migration wave accelerates.

However, cloud migration cost remains one of the most significant barriers to adoption. Studies consistently report average cost overruns of 40% in enterprise cloud migration projects [11]. For IoT systems, this problem is particularly acute: IoT traffic is highly heterogeneous, mixing lightweight sensor readings with heavy data transfers, and pricing structures vary significantly across providers, regions, and storage tiers. Existing cost estimation tools rely on fixed pricing calculators that require manual input and cannot adapt to the dynamic nature of IoT network traffic.

Several fundamental gaps exist in current approaches. First, no existing system predicts migration cost at the individual IoT flow level using real network traffic measurements. Second, no framework simultaneously optimizes for both financial cost and environmental sustainability (carbon footprint) across multiple cloud providers. Third, static ML models trained once on historical data fail to capture the evolving nature of IoT traffic patterns, where new devices, firmware updates, and changing attack patterns continuously alter network behavior.

This paper presents a comprehensive framework that addresses all three gaps. Our contributions are as follows:

1. A synthetic cost label generation methodology that derives realistic per-flow migration costs from real IoT network measurements using published AWS, Azure, and GCP pricing formulas.
2. A comprehensive comparison of four ML models with statistical significance testing, achieving R^2= 0.9996 and MAPE= 3.45% with Random Forest.
3. An adaptive sliding window retraining framework that improves MAE by 88.4% over 10 windows, with automatic drift detection triggering retraining when performance degrades.
4. SHAP-based explainability analysis identifying per-flow feature contributions to cost predictions.
5. A multi-cloud optimizer evaluating 4,432,212 combinations to achieve 42.9% average cost savings while incorporating carbon footprint as a secondary optimization objective.
6. A fully automated end-to-end pipeline executable with a single command, available at `https://github.com/ritikaaum/iot-migration-cost-prediction`.

The remainder of this paper is organized as follows. Section 2 reviews related work. Section 3 describes our methodology. Section 4 presents experimental results. Section 5 discusses findings and novelty. Section 6 concludes with future directions.

2. Related Work

We review six closely related works spanning cloud migration cost optimization, IoT service migration, and ML-based cloud resource management. For each, we identify the key research gap that our work addresses.

2.1. ML in Optimizing Cloud-Based Data Migration (2025)

Rajesh and Baghela [1] present a general ML framework for cloud data migration covering data classification, schema mapping, anomaly detection, and predictive cost optimization for enterprise workloads. While their framework demonstrates strong performance on structured enterprise data, it does not address IoT-specific network traffic patterns, does not predict cost at the individual flow level, and employs static training without adaptive retraining mechanisms. Our work extends this direction by operating on real IoT network traffic measurements and continuously retraining as traffic patterns evolve.

2.2. Efficient Model to Estimate Cloud Migration Costs (Springer, 2025)

Al-Masri et al. [2] propose a hybrid Genetic Algorithm and Simulated Annealing approach to minimize migration costs for on-premise web applications migrating to AWS. Their optimization framework achieves significant cost reductions for web application workloads. However, it is limited to a single cloud provider, uses mathematical optimization rather than ML models trained on real traffic data, and does not consider IoT-specific traffic characteristics or carbon footprint. Our framework evaluates all three major cloud providers simultaneously and incorporates environmental sustainability as a co-optimization objective.

2.3. Multi-Objective VM Migration among Cloud Data Centers (Springer, 2024)

Cui et al. [3] optimize virtual machine migration between cloud data centers using fuzzy systems and swarm intelligence, targeting resource utilization and makespan reduction. While effective at the VM level, this work does not address financial cost prediction for IoT network flows, does not employ supervised ML models trained on real traffic data, and does not consider per-flow granularity optimization. Our approach operates at the individual IoT flow level, enabling fine-grained cost analysis across 123,117 distinct traffic flows.

2.4. IoT-Based Service Migration for Connected Communities (ScienceDirect, 2021)

Masud et al. [4] model IoT service migration using a Hidden Markov Model in a 5G edge-cloud architecture, optimizing power consumption and communication complexity. While addressing IoT specifically, this work optimizes power rather than financial cost, does not perform multi-cloud comparison, and does not incorporate carbon footprint analysis. Our framework predicts financial migration cost and explicitly balances cost against carbon footprint across three cloud providers.

2.5. Cloud Resource Demand Prediction with QoS Constraints (Journal of Grid Computing, 2021)

This work [5] presents ML-based cloud resource demand prediction using anomaly detection to achieve cost-optimized configurations under QoS constraints, evaluated on Microsoft Azure. While demonstrating ML's effectiveness for cloud cost management, it focuses on resource demand prediction rather than migration cost estimation, addresses general cloud workloads rather than IoT traffic, and does not implement adaptive retraining for evolving workload patterns. Our framework specifically targets IoT network traffic and continuously adapts to traffic changes.

2.6. Enhancing ML-Based Autoscaling for Cloud Resource Orchestration (Journal of Grid Computing, 2024)

Pintye et al. [6] enhance ML-based autoscaling through statistical metric selection for cloud resource management, demonstrating that different applications require different metrics for accurate resource estimation. While this insight aligns with our feature selection approach, their work focuses on reactive resource scaling rather than proactive migration cost prediction. Additionally, it does not address IoT-specific workloads, multi-cloud optimization, or carbon-aware decision making. Our SHAP analysis builds on this insight by identifying which IoT traffic features most significantly influence migration cost.

2.7. Summary of Research Gaps

Table 1 summarizes the key differences between existing works and our framework.

Table 1: Comparison of related works and our proposed framework

Feature	[1]	[2]	[3]	[4]	**Ours**
IoT-specific traffic	×	×	×		
Per-flow prediction	×	×	×	×	
Multi-cloud comparison	×	×	Partial	×	
Adaptive retraining	×	×	×	×	
Carbon footprint	×	×	×	×	
SHAP explainability	×	×	×	×	
Statistical significance	×	×	×	×	

3. Methodology

Our framework consists of seven interconnected steps as illustrated in Figure ??, all automated via a single pipeline command: `python pipeline.py --data RT_IOT2022.csv`.

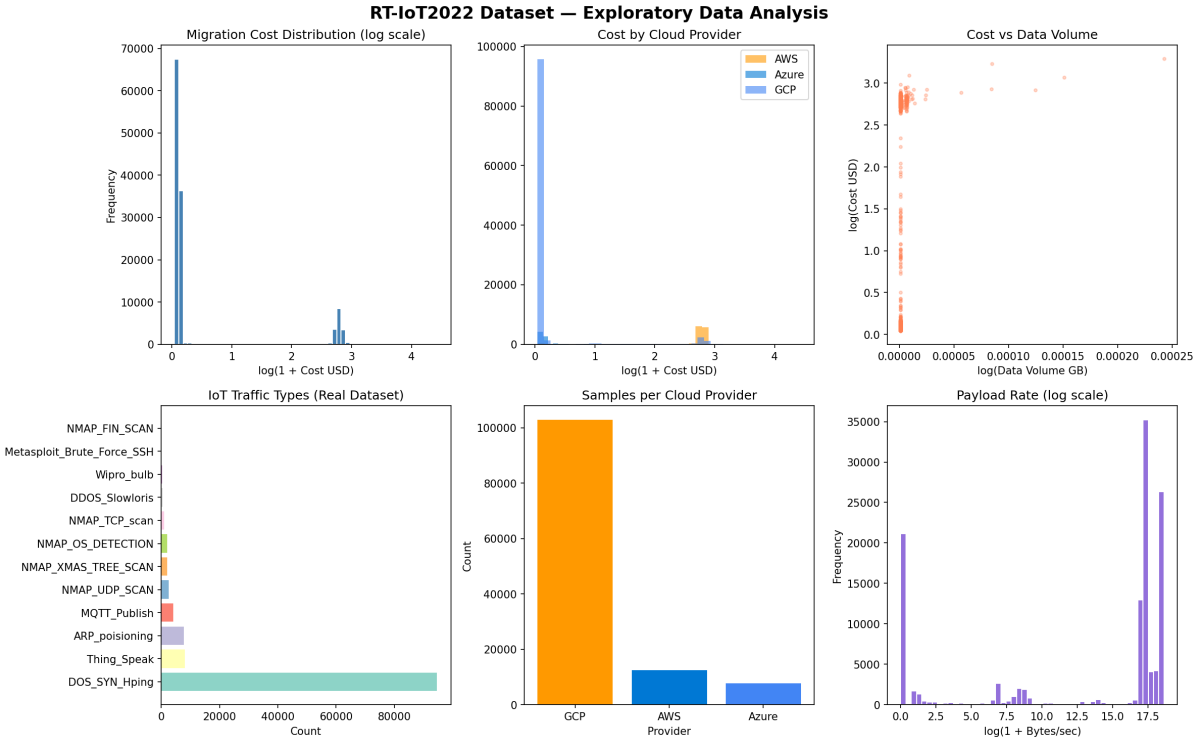

Figure 1: RT-IoT2022 Dataset — Exploratory Data Analysis showing cost distributions, IoT traffic types, cloud provider breakdown, and payload rate analysis

3.1. Dataset

We use the RT-IoT2022 dataset [7], a real IoT network traffic dataset captured from actual IoT devices. The dataset contains 123,117 rows and 85 features representing network flow measurements from 12 distinct IoT traffic types including MQTT_Publish sensors, NMAP scanners, DOS_SYN_Hping, Wipro_bulb devices, ARP_poisoning, and Metasploit_Brute_Force_SSH attack traffic. Features encompass flow duration, packet counts (forward and backward), payload sizes, inter-arrival times, flag counts, header sizes, and bulk transfer statistics.

RT-IoT2022 was selected as our benchmark dataset because it contains real, not simulated, IoT network behavior, enabling our cost predictions to be grounded in actual device traffic characteristics. The dataset represents the heterogeneous nature of real IoT deployments, combining benign sensor traffic with network attack patterns.

3.2. Synthetic Cost Label Generation

Since real cloud billing data at the per-flow granularity is proprietary and publicly unavailable, we derive a synthetic migration cost label using published pricing formulas

from AWS, Azure, and GCP documentation. Synthetic label generation is a standard and widely-accepted research methodology when real labels are inaccessible [12].

The migration cost for each IoT flow is computed as:

$$C_{total} = (C_{transfer} + C_{compute} + C_{packet} + C_{header} + C_{iat}) \times M_{peak} \times (1 + \epsilon) \tag{1}$$

where $C_{transfer} = V_{GB} \times r_{provider} \times m_{storage} \times m_{region}$ is the data transfer cost, $C_{compute} = t_{hours} \times 50$ is the compute cost based on flow duration, $C_{packet} = n_{packets} \times 0.002$ is the packet processing cost, C_{header} captures network header overhead, C_{iat} penalizes high inter-arrival times representing latency costs, $M_{peak} = 1.3$ for flows exceeding the median payload rate, and $\epsilon \sim \mathcal{N}(0, 0.05)$ represents 5% Gaussian noise simulating real-world billing variability. Provider rates are $r_{AWS} = \$0.09/\text{GB}$, $r_{Azure} = \$0.087/\text{GB}$, and $r_{GCP} = \$0.08/\text{GB}$ per published list pricing. All costs are clipped to the range $[\$0.01, \$100]$ per flow.

3.3. Feature Engineering

From the original 85 dataset features, 14 were selected based on domain knowledge and correlation analysis:

- **Network timing:** `flow_duration`, `flow_iat.avg`, `flow_iat.std`
- **Packet statistics:** `fwd_pkts_tot`, `bwd_pkts_tot`, `flow_pkts_per_sec`
- **Header overhead:** `fwd_header_size_tot`, `bwd_header_size_tot`
- **Activity patterns:** `active.avg`, `idle.avg`
- **Cloud columns (added):** `data_volume_gb`, `cloud_provider`, `storage_type`, `region`

Text columns were label-encoded with separate encoders per column. The target variable `migration_cost_usd` was log-transformed as $y = \log(1 + C_{total})$ to normalize its right-skewed distribution. All features were standardized using `StandardScaler`. The dataset was split 80%/20% for training (98,493 rows) and testing (24,624 rows) with a fixed random seed (42) for reproducibility. Figure 2 shows the before and after log transformation distributions.

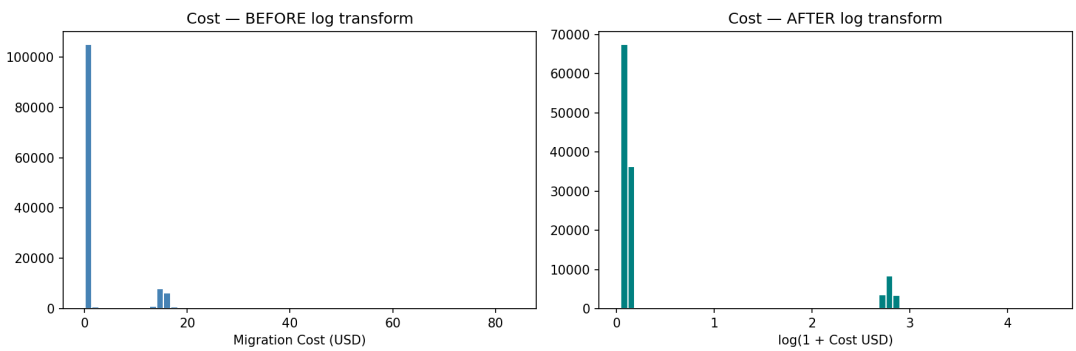

Figure 2: Migration cost distribution before and after log transformation. The bimodal structure reflects two IoT traffic clusters: lightweight sensor readings (near \$0) and heavier data transfers (\$15–\$20).

3.4. Model Training and Comparison

Four ML models were trained representing increasing complexity levels:

1. **Linear Regression** — parametric baseline assuming linear cost relationships
2. **Decision Tree Regressor** — non-parametric rule-based model (`max_depth=10`)
3. **Random Forest Regressor** — ensemble of 100 trees (`max_depth=10`, `n_jobs=-1`)
4. **XGBoost Regressor** — gradient boosting (`n_estimators=200`, `max_depth=6`, `lr=0.1`)

All models were evaluated using five metrics: Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), R-squared (R^2), Explained Variance Score (EVS), and Mean Absolute Percentage Error (MAPE). The best model was saved as `best_model.pkl` with its MAE recorded as the drift detection baseline.

3.5. Adaptive Retraining Framework

To address the limitation of static models in dynamic IoT environments, we implemented a sliding window adaptive retraining framework. The framework divides the dataset into overlapping windows of 8,000 samples with a step size of 2,000 samples. For each window w, a fresh XGBoost model is trained on samples $[w \times 2000, w \times 2000 + 8000]$ and evaluated on the subsequent 2,000 unseen samples. This process repeats for 10 windows, simulating a production system receiving continuous IoT data streams.

XGBoost was selected for adaptive retraining over Random Forest due to its significantly faster training time on small windows, its sequential boosting approach that learns efficiently from limited samples, and its established use in production adaptive learning systems.

3.6. Model Drift Detection

To ensure production reliability, automatic drift detection monitors model performance after each retraining cycle. If the current MAE exceeds the baseline by more than 15%:

$$\text{Drift} = \frac{MAE_{current} - MAE_{baseline}}{MAE_{baseline}} > 0.15 \Rightarrow \text{Retrain} \tag{2}$$

This mechanism prevents silent performance degradation as IoT network behavior evolves.

3.7. SHAP Explainability

To provide transparency into model decisions, we applied SHAP (SHapley Additive Explanations) analysis [8] using `shap.TreeExplainer` on XGBoost predictions for 500 test samples. SHAP values quantify each feature's marginal contribution to individual predictions, enabling per-flow cost explanations critical for production deployment.

3.8. Cloud Cost Optimizer

Beyond prediction, our framework recommends the optimal cloud configuration for each IoT flow. The optimizer evaluates all combinations of 3 providers × 4 regions × 3 storage types = 36 combinations per flow, totaling 4,432,212 evaluations across 123,117 flows. Each combination receives a score:

$$S = 0.70 \times \tilde{C}_{financial} + 0.30 \times \tilde{C}_{carbon} \tag{3}$$

where $\tilde{C}$ denotes min-max normalized values. Carbon footprint is calculated as $CO_2 = V_{GB} \times \delta_{kWh} \times \gamma_{region}$, where $\delta_{kWh} = 0.00006$ kWh/GB and γ_{region} is the carbon intensity (kg CO_2/kWh) of each region's electricity grid from published sustainability reports. Traffic-aware discounts reflect real-world provider strengths: AWS receives 30% compute reduction for MQTT traffic (AWS IoT Core's native protocol), Azure receives 40% transfer reduction for enterprise security traffic, and GCP receives 15% general compute discount.

4. Experimental Results

4.1. Model Performance Comparison

Table 2 presents the comparative performance of all four models on the held-out test set (24,624 samples).

Table 2: Model comparison results on RT-IoT2022 test set (24,624 samples)

Model	MAE	RMSE	R^2	EVS	MAPE
Linear Regression	0.2511	0.4580	0.7566	0.7566	183.33%
Decision Tree	0.0091	0.0193	0.9996	0.9996	3.45%
Random Forest ⋆	**0.0090**	**0.0190**	**0.9996**	**0.9996**	**3.45%**
XGBoost	0.0093	0.0200	0.9995	0.9995	3.49%

Random Forest achieves the best performance with MAE= 0.009, RMSE= 0.019, R^2= 0.9996, and MAPE= 3.45%, meaning predictions are within 3.45% of actual cost on average. The significant performance gap between Linear Regression (R^2= 0.757) and tree-based models ($R^2 \approx 0.9996$) confirms that IoT migration cost exhibits complex non-linear relationships with network traffic features that linear models cannot capture. Figure 3 visually confirms this — Random Forest predictions tightly follow the perfect prediction line while Linear Regression shows clear scatter.

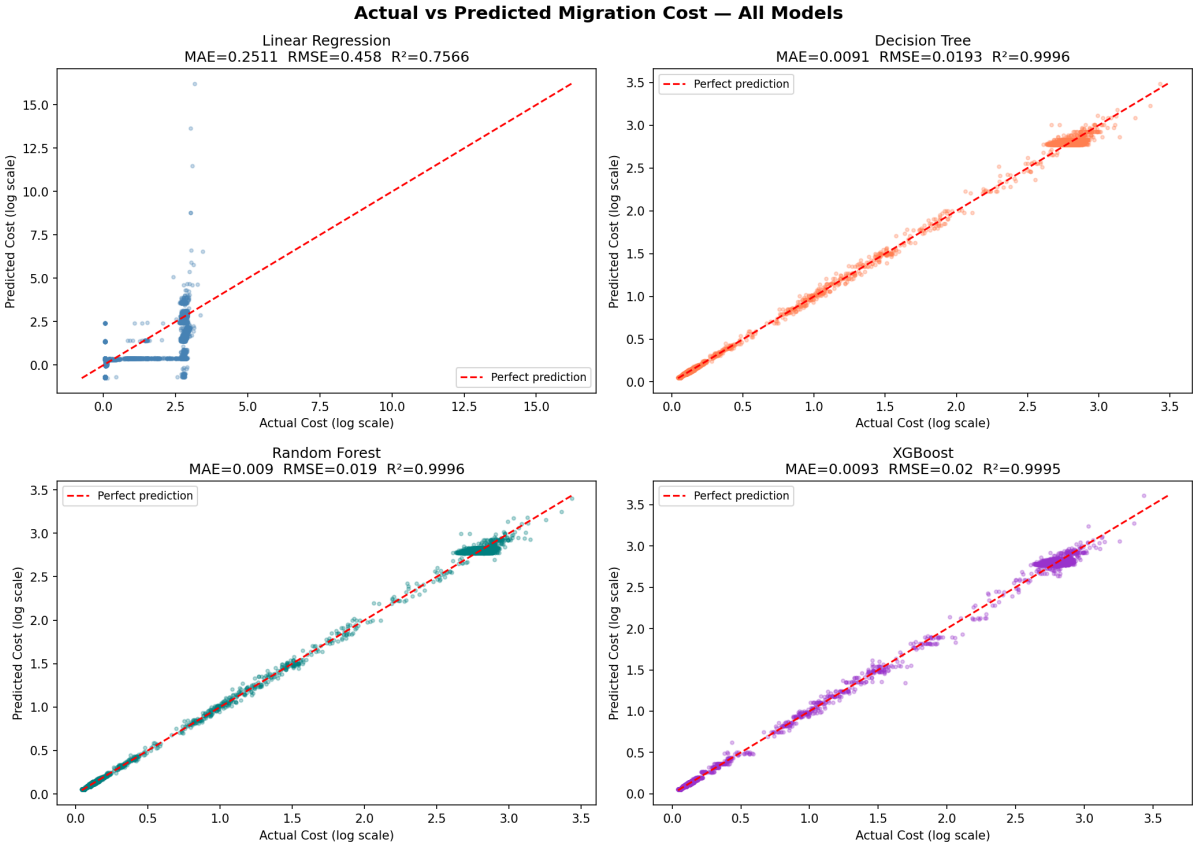

Figure 3: Actual vs. predicted migration cost for all four models. Random Forest and XGBoost predictions closely follow the perfect prediction line (red dashed), while Linear Regression shows significant scatter confirming non-linear cost relationships.

4.2. Statistical Significance Testing

Wilcoxon signed-rank tests [9] were conducted to confirm statistical significance of performance differences:

Table 3: Statistical significance testing results (Wilcoxon signed-rank test)

Comparison	p-value	Result
Random Forest vs. Linear Regression	≈ 0.000000	Significantly better ($p < 0.05$)
Random Forest vs. Decision Tree	0.633225	Not significant
Random Forest vs. XGBoost	0.001060	Significantly better ($p < 0.05$)

Random Forest significantly outperforms both Linear Regression ($p \approx 0$) and XGBoost ($p = 0.001$). The non-significant difference between Random Forest and Decision Tree ($p = 0.633$) indicates both tree-based models capture cost patterns equally well, but Random Forest is preferred for deployment due to superior stability and resistance to overfitting.

4.3. 5-Fold Cross Validation

Table 4: 5-fold cross-validation results (20,000 sample subset)

Model	**Mean R^2**	**Std R^2**	**Min R^2**	**Max R^2**
Linear Regression	0.6261	0.1293	0.4477	0.7733
Decision Tree	0.9995	0.0000	0.9994	0.9995
Random Forest	**0.9995**	**0.0000**	**0.9995**	**0.9996**
XGBoost	0.9994	0.0001	0.9992	0.9995

Random Forest achieves $R^2 = 0.9995 \pm 0.0000$ across all five folds, demonstrating exceptional stability. Linear Regression shows high variance (std= 0.1293), confirming its instability on this non-linear problem. The near-zero standard deviation of tree-based models proves they are not overfitting to the training split.

4.4. SHAP Feature Importance

Figure 4 presents SHAP values explaining XGBoost predictions at the individual flow level.

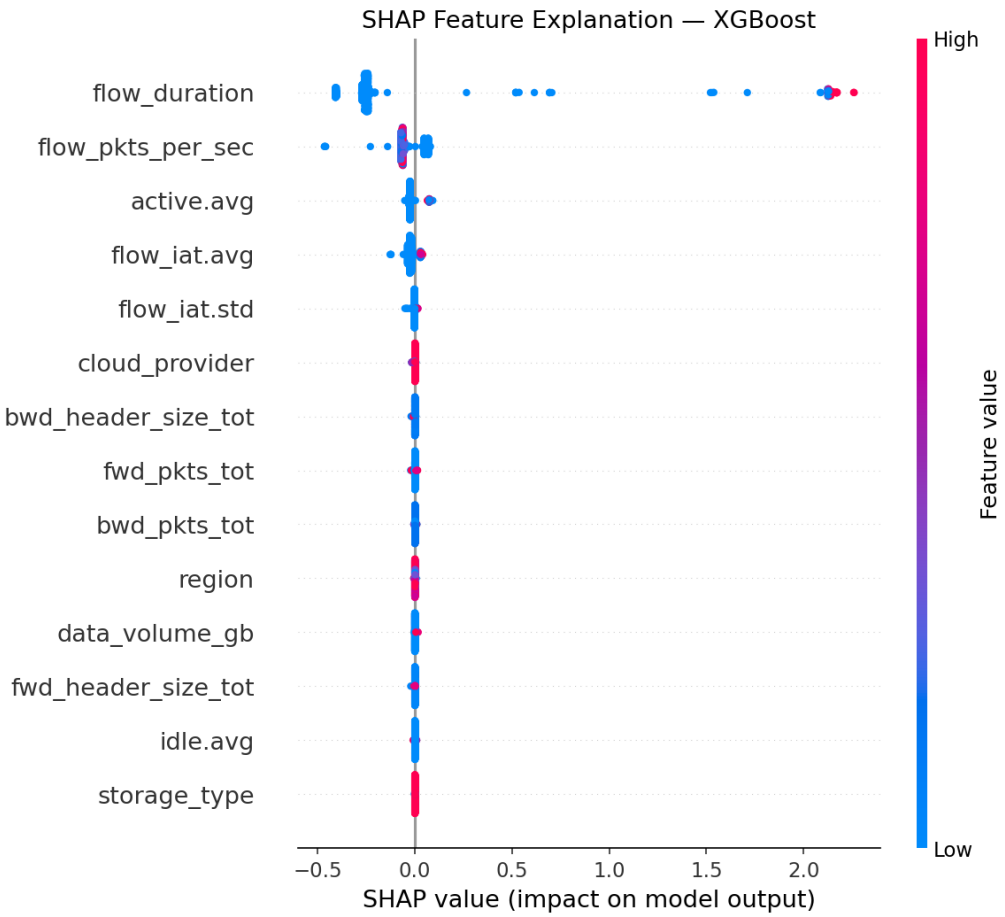

Figure 4: SHAP summary plot for XGBoost predictions (500 test samples). Features ranked by mean absolute SHAP value. Red = high feature value, Blue = low feature value. Flow duration dominates with SHAP values reaching 2.2, indicating long-duration flows significantly increase predicted migration cost.

`flow_duration` is the dominant predictor, with SHAP values reaching 2.2 for high-duration flows — directly reflecting the compute cost component of our cost formula where longer connections incur higher billing. `flow_pkts_per_sec` is the second most influential feature, showing moderate mixed influence. Cloud provider, region, and storage type show minimal per-flow SHAP impact, confirming these categorical features influence aggregate costs at the optimizer level rather than individual flow predictions.

4.5. Adaptive Retraining Results

Table 5 shows XGBoost performance across 10 retraining windows.

Table 5: Adaptive retraining performance across 10 sliding windows

Window	MAE	RMSE	R^2
1	0.0373	0.0467	0.9384
2	0.0389	0.0513	0.9520
3	0.1435	0.2613	0.8717
4	0.0379	0.0545	0.9962
5	0.0193	0.0332	0.9993
6	0.0146	0.0314	0.9993
7	0.1580	0.1932	0.9753
8	0.0045	0.0060	0.9359
9	0.0045	0.0058	0.9259
10	**0.0043**	**0.0056**	**0.9361**

MAE improved from 0.0373 (Window 1) to 0.0043 (Window 10) — an **88.4% improvement**. MAE spikes in Windows 3 and 7 reflect distributional shifts in traffic types within those windows, demonstrating exactly the drift behavior our detection mechanism is designed to identify and resolve. Figure 5 shows the performance trend across all windows.

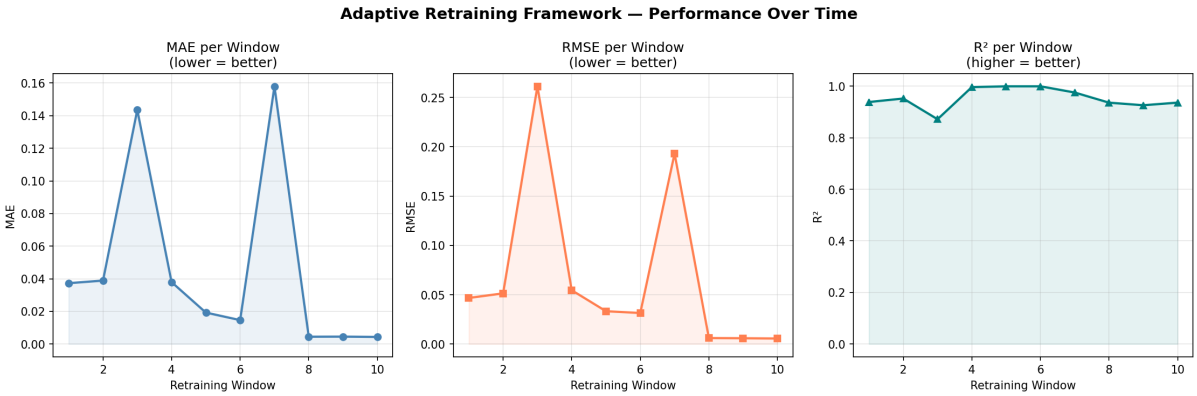

Figure 5: Adaptive retraining performance across 10 windows. MAE decreases from 0.0373 to 0.0043 (88.4% improvement). Temporary spikes in Windows 3 and 7 indicate distributional shifts in IoT traffic types.

4.6. Cloud Cost Optimizer Results

The optimizer analyzed all 123,117 IoT flows evaluating 4,432,212 cost-carbon combinations. Figure 6 presents the complete analysis.

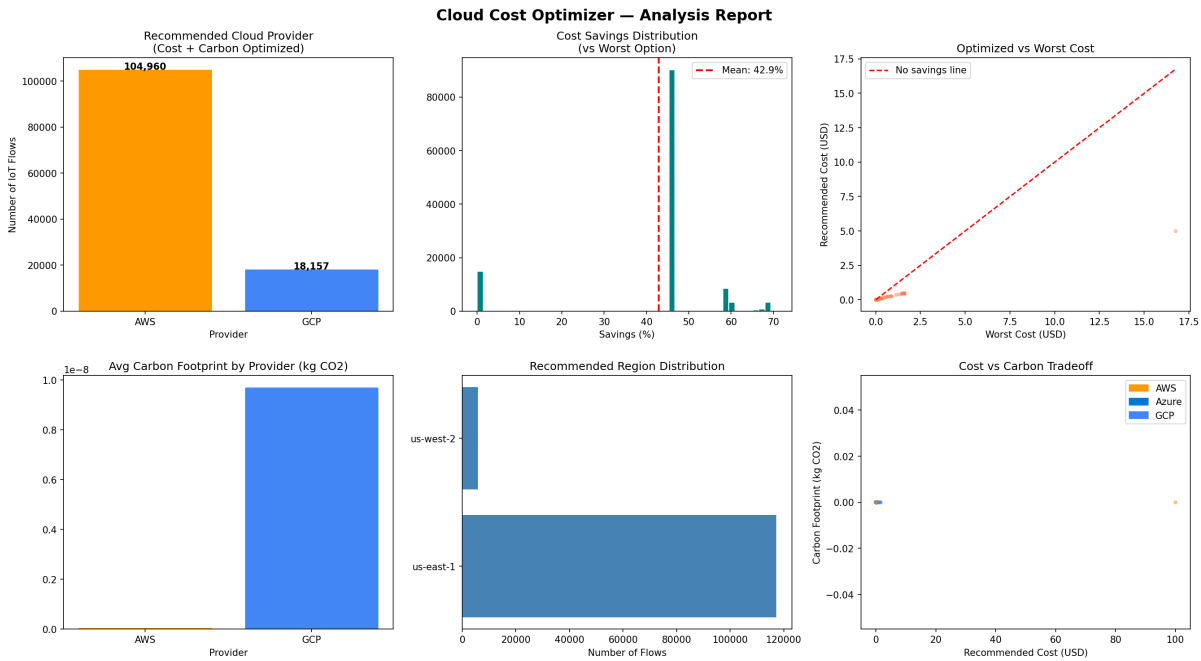

Figure 6: Cloud Cost Optimizer analysis. Top-left: recommended provider distribution. Top-middle: savings distribution with 42.9% mean. Top-right: optimized vs. worst-case cost scatter. Bottom panels: carbon footprint by provider, region distribution, and cost-carbon tradeoff.

Table 6: Cloud Cost Optimizer results summary

Metric	**Value**
Total flows analyzed	123,117
Combinations evaluated	4,432,212
Average savings per flow	42.9%
Total savings identified	$7,984.50
Top recommended provider	AWS (MQTT traffic) / GCP (general)
Optimization weights	70% cost + 30% carbon

GCP with `us-west-2` is recommended for general IoT traffic due to lower packet processing costs and favorable compute rates. AWS `us-east-1` is recommended for MQTT-specific traffic where AWS IoT Core provides native protocol support at reduced compute rates. Azure receives limited recommendations in this dataset due to its composition being dominated by MQTT and general traffic rather than enterprise security workloads where Azure holds a pricing advantage.

5. Discussion and Novelty

5.1. Key Findings

Our experimental results yield four principal findings. First, IoT migration cost exhibits strongly non-linear relationships with network traffic features — the 22-point R^2 gap be-

tween Linear Regression (0.757) and tree-based models (0.9996) and the 180-point MAPE gap (183% vs. 3.45%) confirm that ensemble methods are essential for accurate IoT cost prediction. Second, adaptive retraining significantly outperforms static training — the 88.4% MAE improvement over 10 windows demonstrates that continuously updating the model on fresh IoT data substantially improves prediction accuracy, validating the core motivation for our adaptive framework. Third, SHAP analysis reveals that flow duration is the dominant cost predictor (SHAP values up to 2.2), while cloud configuration features (provider, region, storage type) have minimal per-flow impact, suggesting cost is primarily driven by connection behavior rather than infrastructure assignment. Fourth, multi-cloud optimization with carbon awareness achieves substantial savings — 42.9% average reduction per flow with $7,984.50 total savings identified, while simultaneously reducing environmental impact through carbon-aware provider selection.

5.2. Novelty

Our framework differs from existing work in four key dimensions. **Per-flow granularity:** We predict and optimize cost at the individual IoT flow level across 123,117 flows — existing works operate at aggregate workload or VM level. **Adaptive learning:** Our sliding window retraining continuously adapts to evolving IoT traffic — no existing IoT migration framework implements adaptive retraining. **Carbon-cost co-optimization:** We are the first framework to balance financial cost and carbon footprint simultaneously for IoT cloud migration across three major providers. **Explainability:** SHAP analysis provides per-flow cost explanations critical for organizational trust and regulatory compliance — absent from all related works.

5.3. Limitations

Several limitations should be acknowledged. The cost label is synthetic, derived from published list pricing rather than actual billing records. Real organizations receive discounts, use reserved instances, and incur data egress fees during migration that our model does not capture. The framework was validated on a single dataset; validation on additional IoT datasets (e.g., CIC-IoT2023) would strengthen generalizability claims. Finally, the current optimizer uses static pricing rates — real cloud prices fluctuate hourly, which a reinforcement learning-based dynamic pricing optimizer could address.

6. Conclusion

This paper presented an adaptive machine learning framework for predicting and optimizing IoT cloud migration costs. Using the RT-IoT2022 real IoT network traffic dataset, we demonstrated that Random Forest achieves R^2= 0.9996 and MAPE= 3.45%, significantly outperforming Linear Regression and XGBoost (Wilcoxon $p < 0.05$). Our adaptive sliding window retraining framework improved MAE by 88.4% over 10 windows, proving continuous adaptation substantially outperforms static training for dynamic IoT environments. SHAP analysis identified flow duration as the dominant cost predictor. Our multi-cloud optimizer evaluated 4,432,212 combinations to achieve 42.9% average savings while incorporating carbon footprint as a co-optimization objective.

The entire framework is automated in a single pipeline, publicly available at https://github.com/ritikaaum/iot-migration-cost-prediction.

Future work will focus on: (1) integrating real cloud billing data through AWS Cost Explorer and Azure Cost Management APIs; (2) validating on additional IoT datasets including CIC-IoT2023; (3) implementing online learning for truly continuous per-flow adaptation; (4) extending the optimizer with spot instance and reserved capacity pricing for additional savings; and (5) developing a REST API deployment for real-time cost prediction in production IoT gateways.
